Abstract

While some theories of cognitive control suggest a tradeoff between stable task representations and adapting flexibly to new ones, empirical evidence is inconclusive and has rarely covered the different levels on which such tradeoffs could occur (Egner, 2007; Goschke, n.d., 2000; Rogers & Monsell, 1995). A smaller body of research supports a different account of stability-flexibility, where on the level of within-subject dynamics stability and flexibility are found to co-occur (U. Mayr, Kuhns, & Hubbard, 2014). This raises the question that the stability-flexibility tradeoff seen through experimental level effects is not a fundamental property of cognitive control but may instead reflect the analytic level at which it is measured. Moreover, individual differences work hints at substantial variability in how people balance stability and flexibility, suggesting that the relationship may not be uniform across all individuals (Ulrich Mayr & Grätz, 2024).

We used here a particularly sensitive test of tradeoffs, namely by relating task-switching costs to demands on pre-switch stability (by manipulating task conflict), and we simultaneously examined (a) average experimental effects, (b) within-subject, trial-to-trial dynamics, and (c) inter-individual relationships. Across two experiments (Exp 1: N=100, Exp. 2: N=78) we found no consistent tradeoff relationships on the level of experimental effects while within-subject dynamics revealed increased switch-costs following particularly stable pre-switch trials. On the inter-individual level however, we found a clear anti-tradeoff pattern: Individuals with greatest pre-trial stability showed also greatest flexibility. By showing that stability-flexibility dynamics vary across analytic scales, our results challenge the presumed ubiquity of the dominant tradeoff view and highlight the necessity of multi-level approaches for understanding the mechanisms that govern cognitive control.

Desperately Seeking Stability-Flexibility Tradeoffs: Relating Switch-Costs To Pre-Trial Stability Across Levels of Analysis

Introduction

A dominant view in research on cognitive control holds that adjustments of control are constrained by a general stability-flexibility tradeoff. Specifically, increasing the stability of a task-relevant representation makes flexible changes of that representation more difficult (Goschke, 2000). You may have spent weeks memorizing a speech word-for-word reflecting high stability, but falter when mid-talk someone raises a question, forcing you to switch into an improvised, conversational mode thereby reducing flexibility. The very thing that keeps you anchored can also slow you down when you need to pivot. This negative relationship is grounded in connectionist models of cognitive control, which describe task switching within an “attractor landscape” (*Fig. 1*) (Brown, Reynolds, & Braver, 2007; Geddert & Egner, 2022). Different task representations form basins in a state space, and the depth of a basin reflects how strongly a task is currently activated. A deeper basin corresponds to a more stable task state, but it also requires more “energy” to move out of, making task switching more difficult.

Attractor Landscape Model

Figure 1. The landscape attractor model. Tasks are represented as basins of varying depth along a state space. More stable task representations have deeper basins in this attractor model taking more potential energy to flexibly switch to a different task.

While foundational theories of cognitive control suggest such a tradeoff, empirical evidence collected over the years are inconclusive and has rarely covered the different levels on which such tradeoffs could occur (Goschke, n.d., 2000; Rogers & Monsell, 1995). Most empirical work has examined the stability–flexibility dilemma using blockwise manipulations, contrasting “stable” versus “flexible” blocks in a task-switching context by manipulating response level conflict and switch-frequency. As Egner has argued, these two manipulations might affect different hierarchical levels of control. It is not clear whether tradeoff patterns could be observed when contrasting demands occur on the same level (Egner, 2007). For this reason we manipulated control demands directly on task level through using either univalent stimuli (associated only with one task) or bivalent stimuli (associated with two competing tasks).

The notion of a stability-flexibility tradeoff is typically applied in an indiscriminate manner, painting differences from trial level, individual differences, cultural phenomena, and psychiatric disorders with the same broad brush (Armbruster, Ueltzhöffer, Basten, & Fiebach, 2012; Cepeda, Cepeda, & Kramer, 2000; Colzato, Beste, & Zhang, 2022; Colzato, Hommel, Zhang, Roessner, & Beste, 2022; Cools et al., 2009; D’Cruz et al., 2013; Moss, Kikumoto, & Mayr, 2020; Tajik-Parvinchi, Farmus, Tablon Modica, Cribbie, & Weiss, 2021). Sources of variability across levels of analysis are logically distinct, and systematic analysis of tradeoff phenomena across levels has been rarely conducted. The current study examines tradeoff relationship on the experimental effects (through mean differences), within-subject variability across trials, and average variability across individuals. The later inter-individual differences level requires additional considerations. In previous work (Geddert & Egner, 2022) inter-individual tradeoffs have been examined by directly relating factors representing stability and flexibility. This approach ignores the potential contamination of each measure through the “positive manifold” of positive correlations between almost any cognitive task. It is therefore important to carefully control for such positive “baseline” correlations when testing for potential tradeoff relationships at this level. SEM provides a principled way to

address this issue by removing the positive-manifold variance shared across tasks and isolating the construct-specific variance that reflects genuine stability–flexibility dynamics.

The Current Study. Across two experiments, we used a task-switching ‘shape’ or ‘color’ task with both univalent and bivalent stimuli included to manipulate task conflict. We manipulated these cognitive demands on pre-switch to post-trial for a more detailed measure of how stability-flexibility interact. The main component of experiment 1’s task design was the alternating sequence of four consistent trials per task, which on the one hand offers strong experimental control, also introduces group-to-group consistency. This may increase strategic adaptation, where participants adjust their control settings in anticipation of upcoming task demands rather than responding dynamically to each trial. Experiment 2 adopts a more run-by-run design in which task and stimulus conditions varied in a group of 3 trials than in fixed groups of 4 to account for this possible adaptation effect. We examine these cognitive demands across three complementary levels of analysis consistent across both experiments: (a) average experimental effects, (b) within-subject, trial-to-trial dynamics, and (c) inter-individual relationships. At the experimental-effects level, we test whether manipulations of previous- and current-trial control demands interact with the switch contrast in a manner consistent with a stability–flexibility tradeoff. At the within-subject level, we assess whether trial-by-trial RT autocorrelations, considered alongside the experimental effects, reveal evidence of a tradeoff in moment-to-moment adjustments. Finally, at the individual-differences level, we use structural equation modeling to examine whether variability in measures of stability and flexibility aligns with the predictions of the tradeoff model. Through this multi-level approach, we directly test whether the stability–flexibility tradeoff emerges consistently across analytic levels or whether different levels reveal distinct patterns.

Experimental Level Hypotheses. We hypothesize that 1) previous trial-group bivalence enforces stability and should therefore cause higher switch costs (longer response times, more errors). If the previous group of trials was univalent, previous performance will

require less stability and should therefore reduce switch costs (lower response times, fewer errors). 2) Current-trial bivalence requires establishing a stronger task set and therefore further increases RT and errors. Previous and current ambiguity should produce particularly large switch costs (e.g., an interaction between previous and current ambiguity).

Within-Subject Level Hypotheses. On the level of individual trials, we are testing whether greater stability leads to greater switch-costs in the subsequent task. Where previous trial stability through bivalence will cause high switch cost, particularly when switching from a bivalent to a bivalent trial (high stability will cause low flexibility). Specifically, we expect a negative coefficient for pre-switch response times by pre-switch conflict and task switch status. This is a more stringent test of the stability-flexibility tradeoff predicted on the experimental level; on this level, we examine if the tradeoff is only revealed when you are particularly fast on previous trials.

Inter-individual Differences Level Hypotheses. We test the hypothesis derived from the tradeoff model that 1) participants who are stable under a no-switch condition, which should be more challenging if the previous trials and/or the current trial is bivalent, should be less efficient on switch trials. Because efficiency in almost all cognitive tasks is positively related (i.e., the “positive manifold”) we will conduct a series of model tests, where on each level we will control for relationships occurring on “preceding” conditions to present less of a challenge to the stability-flexibility tradeoff. 2) We predict that with an increase in stability demands (e.g., non-switch trials where the previous and/or current trial group were bivalent), the coefficients should turn negative in case of a tradeoff.

Method

Participants

Our sample size for experiment 1 was 100 (N=100), and the sample size for experiment 2 was 78 (N=78). Both experiments subject were collected using convenience sampling methods recruited from the human subjects pool from the University of Oregon. Participants

signed an informed consent form given by our lab, then were instructed through the experiment ahead. Upon learning the instructions, participants completed one practice block, then proceeded to the start of the experiment. Upon completion of the experiment, subjects were debriefed and thanked for their time.

Procedure

Across both experiments, we had the same basic task stimuli with key design differences that we will discuss after setting up the commonalities in structure.

Stimuli and Variables. The task involved the subject viewing a colored shape. The stimulus dimension shape and stimulus dimension color were consistent across both experiments 1 and 2, with 3 possible shapes appearing (circle, square, and triangle) as the bivalent stimuli, plus a neutral univalent shape which was a cross. The stimulus shapes were also 3 possible colors (red, green, and blue), with the neutral univalent color being gray. In no condition both univalent dimensions were shown. Per trial, subjects completed one of two tasks, one task, “color” determined what color the stimuli is and “shape”, determined the shape of the presented stimuli. Across both experiments, we were interested in the stimulus dimension shape, the stimulus dimension color, and the sequence position in a group of trials, where the first position versus the remaining position serving as the switch contrast. Sequence position in group changed across both experiments, for experiment 1 there were 4 positions per group whereas experiment 2 had 3 positions.

Experiment 1. Subjects performed one of two tasks indicated by task instructions “color” or “shape”, where they identified either the color or shape attribute of a presented stimulus. The task switched every 4 trials, where the first trial of every group always marked a task switch into another group of 4 trials. Similar to the alternate cues experimental design, the univalent aspect was manipulated randomly in a between trial groups design, in this case with all four trials in one group being bivalent or all four trials in one group being univalent, so that the participants knew that the stimuli alternated task dimension in groups

of four. Subjects completed a total of 8 blocks excluding a practice block, each block containing 112 trials.

Experiment 2. In each group, the task remained to be univalent or bivalent, with a task switch after each group of 3 trials. Therefore, for each group, the currently irrelevant task could be either univalent or bivalent, and remained the same per group. The experiment was a task switching paradigm, wherein participants switched between a color and a shape task. In each trial, participants performed one of two tasks- color or shape, where they identify the color or shape of the stimulus, respectively. The task switches every three trials. In other words, the color or shape tasks were active for three consecutive trials. Three trials make up a group. Thus, the first trial of a group marks a task switch into the other task, the following two trials are task repetitions. There was a 100 ms Inter-trial-interval. The participants performed one initial practice block with 126 trials and then moved onto performing 5 experimental blocks with 120 trials each.

Analysis and Results

Our analysis plan was consistent across both experiments and outlined in a *preregistered project* found here (link to preregistration). Across both experiments, our exclusion criteria for subjects were accuracy rates below a threshold of 80% accurate across the entire experiment and excluding a practice block that occurred at the beginning of both experiments. In terms of response times, we identified outlier observations through excluding all trials with reaction times having a z-score greater or lower than 3. Outside of our exclusionary criteria, we note that in some models we used, particularly when conducting our within-subjects modeling, we ran into issues of convergence and/or singularity across both experiments. As a result, we conducted a pre-set series of model comparisons detailed below to achieve the most complex model for each experiment that did not have any convergence or singularity issues. We outline the analysis stream for how we conducted our model comparison tests for this in our *supplementary materials*.

Experimental Level Analysis.

Analyses of the dependent variables were conducted on the trial level using multilevel modeling. Independent models for response times and error rates were fit according to the valence (univalent, bivalent) of the previous trial group, the valence of the current trial group, and the switch condition. We outline the models we used in the *pre-registration* which can be found ([link to preregistration](#)).

Figure 2. Average Experimental Effects of logged response times and error rate on previous to current trial valence (uni- or bivalent) and trial type (switching trial or repeat trial).

Experimental Level Results.

Experiment 1 is inconsistent across variables, with response time revealing a weak anti-tradeoff, error rate a tradeoff relationship. Where in logged response times, we see a significant interaction occurring between current trial valence and task switching (est = 0.03, $p = 0.002$). When examining error rate, we see a tradeoff occurring with the same interaction, current valence and task switching (odds ratio: 2.24, $p < 0.001$). Experiment 2 finds a weak tradeoff relationship occurring in response time and error rate. Specifically, logged response times reveal a significant interaction between previous trial valence and task switching (est = 0.01, $p = 0.033$), and a significant 3-way interaction with current trial valence, previous trial valence, and task switching (est = -0.11, $p < 0.001$). Error rate models for experiment 2 reveal a significant interaction between current trial valence and task switching (odds ratio: 1.18, $p = 0.009$), as well as previous trial

valence and task switching (odds ratio: 1.17, $p = 0.014$). Across the two experiments, we cannot clearly identify a trend how stability-flexibility are related, and therefore on the experimental level we conclude results to be largely inconclusive.

Within-Subjects Level Analysis. At the within-subject level, we assessed whether trial-by-trial response time autocorrelations, considered alongside the experimental effects, reveal evidence of a tradeoff in moment-to-moment adjustments. We used a residualized pre-switch logged response time as our predictor variable (residualizing out both the general trends and task) for ($n-1$ bivalent, $n-1$ univalent), current-trial valence (n bivalent, n univalent), and switch condition (switch trial, no-switch trial).

Within-Subjects Level Results. Across both experiment 1 and 2, we see a tradeoff occurring. Previous trial bivalence has a significant interaction with task switching and previous response times (experiment 1: $est = -0.10$, $p < 0.001$; experiment 2: $est = -0.07$, $p < 0.001$). As seen in *figure 3*, when subjects are coming from a particularly stable trial (lag RT slow), they have a hard time switching, especially into a bivalent trial. Contrary to our hypothesis however, we see that in experiment 1 when coming from a slow performing trial, response times are largest when going from a univalent to a bivalent trial. This finding was not replicated in experiment 2 however but across both, there doesn't seem to be a significant distinction of a previous trial bivalent to current bivalent trial having the largest switch cost. Instead, a better predictor when coming from a slow stable trial is current trial bivalence.

Figure 3. Within-Subject Dynamics of trial-by-trial logged response time autocorrelations on previous to current trial valence (uni- or bivalent) and trial type (switching trial or repeat trial). Split for visualization purposes into previous fast and slow response times by experiment.

Inter-individual Differences Level Analysis. Individuals' reaction time and error data were aggregated for all crossings of previous-trial group valence (n-1 bivalent, n-1 univalent), current-trial valence (n bivalent, n univalent), and switch condition (switch trial, no-switch trial). Reaction times were averaged across the no-switch trials within each trial group. Each trial group consisted of three trials for the alternate-cues experiment and four trials for the alternate-runs experiment. Individual differences analyses of the dependent variable were conducted using linear regression modeling.

Inter-individual Differences Level Results. In both experiments, we see a strong co-occurrence of stability-flexibility on the inter-individual level. This positive co-occurrence is consistently found across error rates and logged response times. Where in general, individuals who are better at switch trials will also be better at no-switch trials. Additionally, the switch to no-switch bivalent-bivalent pairing, which is the strongest test of switching from stable trial is strongly positive in error rate. This means that people who are good at bivalent-bivalent switch trials will also be better at bivalent-bivalent no-switch trials.

Figure 4. note: not commenting on this figure because we plan to move this analysis to supplementary materials and instead talk about a SEM analysis we also performed

Discussion

We find significant differences in how stability-flexibility are related occurring on every level of analysis. Using a stringent manipulation of pre- to post-trial control demands, our results reveal a more complex picture of stability-flexibility dynamics than predicted by a simple, universal tradeoff model. At the experimental-effects level, neither experiment provides strong evidence for either a tradeoff or an anti-tradeoff pattern. In contrast, within-subject dynamics show a reliable negative relationship: when participants come from a particularly stable task state, they are slower to flexibly switch on the next trial. On the inter-individual level we see yet another change in how stability-flexibility are related, revealing an anti-tradeoff (i.e., a co-occurrence of stability and flexibility), meaning individuals with greatest pre-switch stability also showed greatest flexibility.

The inconclusive findings on the experimental level replicates the findings from egner. . .

Outside of experimental effects, we do not see many studies interested in understanding how stability-flexibility emerges on different levels of analysis. Mayr, Kuhns and Rieter found a positive relationship between stability-flexibility using an eye-tracking task design on the level of within-subject dynamics (U. Mayr, Kuhns, & Rieter, 2013). In our study however, we see a tradeoff occurring in within-sub dynamics. This discrepancy may reflect differences in how stability and flexibility were operationalized, where the Mayr et al. study used a combination of eye-tracking as well as mixed modeling in their methods to understand in a fine-grain manner the dynamic relationship between stability and flexibility within- and across-trials. Interestingly, Mayr et al. found a weak tradeoff of visual spatial attentional setting but not on response times. This points to the notion that it matters how stability-flexibility is represented and created; tasks that evoke stability-flexibility dynamics are not necessarily interchangeable or generalizable.

If we are to believe that we can apply general cognitive processes as a behavior that

applies to the general population, the tradeoff found at the within-subject level should also apply inter-individually. Instead, we find the opposite: a robust tradeoff within individuals but a clear anti-tradeoff (i.e., a co-occurrence of stability and flexibility) across individuals. These findings align with emerging accounts of cognitive control that emphasize structured, map-like representations rather than simple attractor dynamics (Ulrich Mayr & Grätz, 2024). (add more)

Taken together, there seems to not be a unified answer to the stability-flexibility dilemma. Rather than reflecting a universal constraint, tradeoff patterns appear to be contingent on how stability and flexibility are created, measured, and analyzed. Our results challenge the ubiquity of the tradeoff model and point toward the need for a more nuanced framework. We attribute these findings to that the tradeoff model of stability-flexibility is likely not a general phenomenon, instead tradeoffs found are likely a representation of specific phenomenon. Understanding the relationship between stability-flexibility may be better understood through the lens of conjunctive representations (add more).

Supplementary Materials

(write more about our model comparisons decision-tree procedure and how our final models for these ended up looking. can set up here what the procedure was then in each section we describe the ez-ddm models and what our final model looked like, how it differed across exp1 and 2 then again in the within sub section.)

Experimental Effects

These models were run on the data from both experiments. The outcomes of these analyses guided how subsequent analytic layers were approached. We accounted for the possibility of finding evidence for speed–accuracy trade-offs through observation of opposing effects on reaction times and errors but they did not emerge. Consequently, drift-diffusion modeling (EZ-DDM) was applied not as an additional validation of the observed effects and we proceeded with analysis of within-subject dynamics. For the EZ-DDM analysis, the mean and variance of reaction times and mean error rates were calculated for each subject and for the same contrasts specified above. The resulting parameters were analyzed using linear mixed-effects models with random intercepts for each subject to confirm the robustness of the experimental-level findings.

Individual differences analyses of the dependent variable were conducted using linear regression modeling. For each participant, drift rate was computed as a function of switch condition and previous and current group-valence conditions (eight estimates per subject). A stringent test was then performed to determine the presence of a trade-off pattern by adding predictors sequentially. The first model type predicted drift rate in the least-demanding switch condition (univalent-univalent) from the least-demanding non-switch condition (univalent-univalent). Predictors were subsequently added to this model in three steps (see model outline below).

(model outline figure here)

EZ-DDM parameters of non-decision time (T_{er}) and boundary separation (a) were also computed. If the EZ-DDM non-decision time parameter (T_{er}) was negative in fewer than 20% of cases across all subjects and conditions, the linear regression models were re-run with data cells in those conditions set as missing. Results obtained from the drift-rate models were cross-referenced with two additional models: one using log-transformed reaction time as the dependent variable and another using error rate as the dependent variable. These models were implemented identically to the steps outlined above.

(add in ddm model builds with also explanation across both experimtns what models were different and why)
